We studied a feasibility of measuring Higgs boson pair production in a Photon Linear Collider. The optimum energy of $\gamma\gamma$ collision was estimated with a realistic luminosity distribution. We also discussed simulation study for detecting the signal against $W$ boson pair backgrounds.

1 Introduction

As a possible option of the International Linear Collider, feasibility of physics opportunities of high energy photon-photon interaction has been considered. In the high energy photon linear colliders (PLCs), high energy photon beams are generated by inverse Compton scattering between the electron and the laser beams as illustrated in figure 1. Feasibility of the PLC for both physics and technical aspect, has been studied and summarized in [1]. In these study, one assumed integrated luminosity of 3 4 years PLC operation which, for example, may happens after initial operation of $e^+e^-$ mode of the ILC at $\sqrt{s} = 500$GeV.

In this study, we investigated a feasibility of self-coupling of the Higgs boson as an example of a precise measurement with the PLC by assuming an ultimate integrated luminosity, i.e., 10years operation with a high luminosity parameters.

The Higgs boson self-coupling constant is represented by $\lambda = \lambda^{SM}(1 + \delta\kappa)$ which contributes Higgs boson pair production via a diagram shown in figure 2. Here, $\lambda^{SM}$ is Higgs boson self-coupling constant which is included in the Standard Model. $\delta\kappa$ represent the deviation from the Standard Model.

The self-coupling of the Higgs boson can also be studied in $e^+e^-$ collision via the diagram shown in figure 3. Comparing with the $e^+e^- \rightarrow ZHH$ channel, where Higgs boson
pairs are associated with the Z boson production, the Higgs bosons are produced by s channel via loop diagrams in $\gamma\gamma$ collision. Therefore, contribution of the $\delta\kappa$ to the production cross section is difference for the $e^+e^-$ and for $\gamma\gamma$ and studies in these two modes will be complementary each other. Detail of the theoretical background in this analysis can be found in [2].

2 Sensitivity Study

For optimization photon-photon collision energy, we defined the sensitivity for the $\delta\kappa$ as:

$$sensitivity = \frac{|N(\delta\kappa) - N_{SM}|}{\sqrt{N_{obs}}} = \frac{L|\eta \sigma(\delta\kappa) - \eta \sigma_{SM}|}{\sqrt{L(\eta \sigma(\delta\kappa) + \eta \sigma_{SM})}}$$

where, $N(\delta\kappa)$ is a expected number of events as a function of $\delta\kappa$ and $N_{SM}$ is the number of events expected from the Standard Model. $L, \eta, \sigma(\delta\kappa), \sigma_{SM}, \eta_B$ and $\sigma_B$ are integrated luminosity, detection efficiency of signal, cross section with $\delta\kappa$, cross section with the Standard model, detection efficiency for background events and the cross section for background processes, respectively. For $\eta = 1$, $\eta_B = 0$, sensitivity is written:

$$sensitivity = \sqrt{\frac{L|\sigma(\delta\kappa) - \sigma_{SM}|}{\sigma(\delta\kappa)}}$$

The Higgs boson mass of 120GeV and the integrated luminosity of 1000fb$^{-1}$ was assumed in the study. The cross section is calculated by the formula which is described in [3] with a theoretically calculated PLC luminosity spectrum. The sensitivity as a function of the center of mass energy of the $\gamma\gamma$ collision for $\delta\kappa = 1$ and -1 is plotted in figure 4.

From the figure, the optimum energy for the $\gamma\gamma$ collision for Higgs boson mass of 120GeV was found to be around 270GeV.

3 Background

Figure 5 shows cross section as a function of collision energy for photon-photon interactions. Figure 5 indicates that $\gamma\gamma \rightarrow WW$ is main background with the production cross section of about 90pb. On the other hand,
signal cross section is 0.044 fb at optimized energy. Therefore, observation of signal requires background suppression of $10^{-7}$. The other reaction that has large cross section such as $\gamma \gamma \rightarrow WWZ$ and $\gamma \gamma \rightarrow t\bar{t}$. However the optimum energy for $\gamma \gamma \rightarrow HH$ is below these threshold for these channel.

### 4 Simulation Framework

JLC Study Framework (JSF) is used as simulation framework in this study [4].

The helicity amplitude for the signal is calculated by theoretical calculation program [5]. The helicity amplitude for background processes were calculated by a helicity amplitude calculation package; HELAS [6].

The luminosity distribution used in the analysis were generated using the CAIN[7] program with the input parameters shown in table 1 [8]. The luminosity spectrum simulated with the CAIN is shown in figure 6.

From these helicity amplitude and luminosity spectrum, BASES/SPRING integrated and generated events. Pythia made parton shower and hadronized. Quick detector simulator read particle list that from pythia. Finaly, data from Quick Detector Simulator is analyzed.

With this spectrum, we expect signal of 16 event/year, while $10^{7}$ event/year for background.

### 5 Analysis

The decay branching ratio of the Higgs boson of 120 GeV is shown in table 2. Since main decay mode of the Higgs boson of 120 GeV is b-quark pairs with the branching ratio of about 0.67, we tried the case that both Higgs boson decayed into b-quark pairs.

For each event, we applied forced four jets analysis in which a clustering algorithm is applied to an event by changing the clustering parameter until the event is category-
rized as a four jets event. After the forced four jets analysis, invariant masses for jet pairs were calculated. For a four jets event, we must choose a right jets pairs originating from parent Higgs (or W for the background) bosons out of three possible combinations. For this purpose, we defined \( \chi^2 \)'s as:

\[
\chi^2_H = \frac{(M_1 - M_H)^2}{\sigma_{2j_H}^2} + \frac{(M_2 - M_H)^2}{\sigma_{2jH}^2}
\]

\[
\chi^2_W = \frac{(M_1 - M_W)^2}{\sigma_{2j_W}^2} + \frac{(M_2 - M_W)^2}{\sigma_{2jW}^2}
\]

where, \( M_1 \) and \( M_2 \) are reconstructed particle mass, \( M_H \) and \( M_W \) are Higgs boson and W boson mass respectively, with \( \sigma_{2j_H} \) and \( \sigma_{2jW} \) being their resolutions. The jet of the least \( \chi^2 \) was chosen to be the most probable combination for an event. Figure 7 shows correlation of \( \chi^2_H \) and \( \chi^2_W \) for the most probable combination. To enhance Higgs boson from the W boson events, we chose an event satisfies \(-140/20 \times \chi^2_H + 140 \geq \chi^2_W\). The mass distributions for the Higgs and W boson events after \( \chi^2 \) cut are shown in figure 8.

### 6 b-tagging

By the \( \chi^2 \) analysis described in previous section, the W boson background was suppressed by 0.0541 while keeping the 46% efficiency for the Higgs boson events. In order further improve signal to background ratio, we applied b-quark tagging method for remaining events.

Figure 9 illustrates a b-quark tagging method we applied. For each track in a reconstructed jet, \( N_{\text{sig}} = L/\sigma_L \) was calculated, where \( L \) is the least approach to the interaction point of the track in the plane perpendicular to the beam and \( \sigma_L \) being its resolution. Then, \( N_{\text{off}}(a) \), number of track which has \( N_{\text{sig}} > a \), is calculated for each jet as a function of \( a \). In current analysis we required all jets must satisfy \( N_{\text{off}}(3.5) \geq 2 \). Figure 10 is the \( \chi^2 \) plot after b-tagging but before \( \chi^2 \) cuts. We obtained background suppression of \(1.35 \pm 0.18 \times 10^{-6} \) and efficiency of signal of \(0.1454 \pm 0.0044 \), where the errors

\[
\sigma(\gamma \gamma \rightarrow HH) \times 5 \times 10^4
\]

Figure 7: Reconstructed particles \( \chi^2 \) distribution. Black indicates signal events, red indicates background events. Green line is represented by \(-140/20 \times \chi^2_H + 140 \geq \chi^2_W\). Here, to make signal clear, signal cross section is about \(5 \times 10^4 \) times as large as usual.

Figure 8: Reconstructed particle mass spectrum that cutted. Background is suppressed, but not enough.

Figure 9: An outline of nsig method. B-hadron is generated at interaction point and decay at "Decay of b-hadron". Arrows mean particle tracks. Dotted line means extrapolate particle tracks.
are from statistic of the Monte Carlo simulation. For remaining events, $\chi^2$ cut were applied. As a result, no WW events survived out of $3.85 \times 10^7$ simulated events while keeping signal efficiency of $0.1096 \pm 0.0014$.

7 Summary and prospect

We studied feasibility of measurement of Higgs self-coupling constant at the PLC. For Higgs mass of 120GeV, optimum photon-photon collision energy for observe $\gamma\gamma \rightarrow HH$ was found to be about 270GeV. With a parameters of PLC(TESLA-optimistic), 16 events/year is expected for Higgs boson events while main background of $\gamma\gamma \rightarrow WW$ is about $10^7$ events/year.

We tried an event selection with kinematical parameters and b-quark tagging by the simulation and found that background suppression of $10^{-7}$ with keeping signal efficiency of about 10% seemed to be possible.

For further analysis, we plan to improve signal efficiency by:
- optimization of selection criteria for $HH \rightarrow b\bar{b}b\bar{b}$ mode.
- study for $HH \rightarrow b\bar{b}WW^*$ decay.

For the background, it is necessary to estimate contribution from $\gamma\gamma \rightarrow ZZ$ events.
